UNIVERSITY OF THE WEST OF ENGLAND

A MSc dissertation submitted to the University of Bristol  
and the University of the West of England in accordance  
with the requirements of the degree of MASTER OF  
SCIENCE IN ROBOTICS in the Faculty of Engineering.

August 29, 2023

# Declaration of own work

I declare that the work in this MSc dissertation was carried out in accordance with the requirements of the University's Regulations and Code of Practice for Research Degree Programmes and that it has not been submitted for any other academic award. Except where indicated by specific reference in the text, the work is the candidate's own work. Work done in collaboration with, or with the assistance of, others, is indicated as such. Any views expressed in the dissertation are those of the author.

Name and Date

# Acknowledgement

I would like to thank ...

# Abstract

**Abstract should give a short summary of the motivation, the approach and important insights and results.**

Number of words in the dissertation: .... words.

# 1 Introduction

## 1.1 Brief Introduction

The main idea of this project is to employ the principles of a decentralized channel sharing communication protocol (*Self-organised Time Division Multiple Access*, STDMA[1]) to organize agents, and utilize the control strategies of *Distributed Model Predictive Control* (DMPC) to coordinate their movements, aiming to achieve collision-free motion among multiple decentralized agents on a 2D plane.

### 1.1.1 Principles of STDMA

In STDMA, a 1D channel is represented with repeating frames that are consisted of discrete time slots.

STDMA enables agents to achieve **Self-organised Time-Divided Multi-Access** within the channel. That is, each agent independently finds a slot which is uniquely its own and uses this slot to broadcast its message.

**The key idea of STDMA** is to determine empty slots and apply for them.

This idea also works for collision-free moving on 2D plane — to determine free space and apply for usage.

For detailed explanation about STDMA, please see **PLACEHOLDER**.

### 1.1.2 Control Strategy of DMPC

Distributed MPC is a control strategy based on *Model Predictive Control* (MPC).

In MPC, the model of the controlled object is utilized to forecast its outputs. Periodically, a constrained finite horizon optimization problem is solved to derive the control sequence. MPC **implicitly formulates control laws** by imposing constraints (e.g., collision-free) on the optimization

problem, and could **dynamically respond to the external environment changes** (e.g., movement of other agents), rendering it apt for managing the movements of agent.

Distributed MPC evolves from the foundation of MPC by eliminating the centralized controller. Instead, it **relies on the collaboration of multiple decentralized MPC controllers situated on multiple individual agents to achieve the overall system control tasks**. Such a decentralized characteristic aligns with the requirements set forth in this project for collaborative control among decentralized agents.

### 1.1.3 The 2D Plane

The 2D plane used in this project is represented with discrete pixels / grids, just like the STDMA protocol represents continuous time with discrete slots.

For such a representation of a 2D plane, there is a term called **grid world**[2].

For detailed assumptions, please see **PLACEHOLDER**.

### 1.1.4 Agents

To meet the requirement of decentralization, the agents are assumed to be **identical**.

The agents can:

- Broadcast and receive messages in the given channel, but cannot do both at the same time (i.e., cannot be listening while speaking or speaking while listening).
- Move only one step / one grid in the map in one time step.

For detailed assumptions, please see **PLACEHOLDER**.

## 1.2 Aims

- Based on the idea of STDMA and the control strategy of DMPC, design an algorithm for decentralised agents to achieve collision-free movement on 2D plane.

- Assess the advantages and disadvantages of the proposed algorithm, investigate the underlying reasons for these attributes, and thereby gain deeper insights into the problem the algorithm aims to address.
- Offer a reference point for similar design challenges in the future.

## 1.3 Objectives

1. Implement original STDMA communication protocol with ROS2, use nodes in ROS2 as agents in the channel, achieve self-organised channel sharing and communicating among agents.
2. Design the specific algorithmic content based on DMPC for agents to achieve collision-free movement.
3. Implement the designed algorithm with ROS2, use ROS2 nodes as agents moving on the 2D plane.
4. Build proper test scene and performance evaluator that could extract metrics (makespan, average finish time, etc.) from simulations.
5. Examine the advantages, disadvantages and limitations of the designed algorithm, summarize the results from observations.

## 1.4 Motivation

The motivation of this project is to answer a question which is inspired by [3], which is:

**What would happen if use STDMA for decentralized multi-dimensional resource sharing?**

And this question could be separated to the following two parts:

### 1.4.1 Why STDMA?

The reason for using STDMA is its **characteristics**[4]:

1. **Deterministic**: Agents arrange their data transmission based on a determined timetable.
2. **Decentralized**: Agents listen to the channel first, then independently seek and allocate free slots for themselves to use.

These characteristics are useful for multiple agents to achieve collision-free (use free slots only), self-organised (find slots on its own) moving and resource sharing.

There are also **reasons that making this challenging**:

1. **Dimensional Difference**: STDMA is designed for sharing discrete time slots (1D), and cannot be directly applied for resource sharing on a 2D plane (which is actually a 3D sharing problem because the time axis). Modification is needed for 3D application.
2. **Moving by Grids**: In the communication scenario, agents don't have destinations in the timetable, i.e., don't need to move to specific slot in the timetable. But that's different for 2D space moving, where agents have their destinations and need to move grid by grid to reach their goals. Agents could easily be trapped in situations of inefficiency or even deadlock situations [5], [6].

These characteristics and challenges are making this topic interesting and worthy for investigation.

### 1.4.2 Why decentralized resource sharing and path planning?

There are many algorithms aim to solve this problem, and their shared aspect is a **focus on the movement of multiple decentralised agents within a grid world**.

To easily get a better understanding of this problem, please refer to this website<sup>1</sup>. This website presents the problem scenarios and their solutions through a simple and engaging animation (estimated time required: 1~2 min). For detailed explanation, please see **PLACEHOLDER**.

For such situations, **there are myriad corresponding real-life problems and applications**.

<sup>1</sup><https://primalgrid.netlify.app/primal>

<sup>2</sup><https://spectrum.ieee.org/interview-brad-porter-vp-of-robotics-at-amazon>

Figure 1.1: Kiva system operating in Amazon warehouse.<sup>2</sup>

- **Warehouse Automation:** Automated pick-pack-and-ship system in warehouse (like Fig 1.1.) [7]. Delivering items in sorting station[8], [9].
- **Intersection Management:** Coordinate autonomous vehicle movement through intersections [10].
- **Robot Fleet:** Automating fleets of autonomous robots like forklift fleets [11], [12].
- **Agents in video games and CGIs:** Flock simulating and animating[13], [14].
- **Swarm Robots:** Controlling self-organised robot swarms[15].

In general, the application of this algorithm is very broad. Furthermore, in the context of Industry 4.0 and flexible manufacturing, it has even better prospects for application[16]–[18], as centralized control is gradually becoming inadequate to meet new production needs.

## 2 Literature Review

This section provides details on the STDMA[1] protocol, a review of the *Distributed Model Predictive Control* (DMPC) algorithms for controlling multi-agent movements, and a review of other algorithms, specifically the *Multi-Agent Path Finding* (MAPF) algorithms, which address the target problem of this project.

### 2.1 STDMA Explained

As previously mentioned in Section 1.1, STDMA stands for *Self-organised Time-Divided Multiple Access*, and it allows multiple agents to share the same channel for communication without centralised control. The main assumption of this protocol is that all agents have synchronised clocks. In practice, this is achieved through GPS[19].

**The core idea of STDMA could be summarised as follows:** Represent continuous time with repeating frames that are consisted of discrete time slots. While agents are always listening to messages from the channel, they look for free slots to occupy, and therefore use the occupied slots to broadcast their own data.

Agents using STDMA have **four phases**, which are arranged in chronological order as follows:

1. **Initialisation:** Agents in this phase have not yet joined the network. The device listens to an entire frame and determines current allocation of each slot.
2. **Network Entry:** Randomly choose an unallocated slot to broadcast their existence and reserve one slot for the next phase. If the message sent didn't collide with others (i.e., only one agent which is myself choose to use this slot for entering), then the entering is successful. If the entering failed, reverse to the previous phase.
3. **First Frame:** Use the slot reserved in the previous phase to reserve more slots for themselves.

The number of reserved slots depends on the size of the data packet that the agent needs to

send in each frame.

4. **Continuous Operation:** Use the previously reserved slots to work normally. If some slots are released or more slots are needed, reapply for slots.

Although the description above omitted some details (such as slot choosing strategy, calculation of required number of slots, etc.), it is clear that **the core idea of STDMA is the strategy of finding and reserving unallocated slots.**

This protocol also has several limitations, such as: **(1) Collision in entering:** In the Network Entry phase, multiple agents may accidentally choose the same unallocated slot for entering and broadcast their existence. **(2) Capacity:** When slots are not enough, conflicts would inevitably occur. There are some studies [20], [21] that proposed improvements for its limitations, but improving STDMA is not the focus of this project.

For detailed implementation, please see **PLACEHOLDER**.

## 2.2 Distributed Model Predictive Control

*Distributed Model Predictive Control* or DMPC is a control strategy based on *Model Predictive Control* (MPC). In MPC, **conditions and limits are treated as constraints**, and the **control problem is regarded as an optimization problem**. Based on the model of the controlled object, **a constrained finite horizon optimization problem is periodically solved**, resulting in a sequence for system control input. DMPC builds on the foundation of MPC by incorporating decentralized requirements and features. This makes it apt for tackling multi-agent swarm motion control problems, such as: formation control[22], path tracking[23], path planning[24], and obstacle avoidance[25]. The commonality of such problems is that **agents subject to static constraints** (e.g., collision-free, following a designated agent, or adhering to a specified path) **in a dynamic environment** (e.g., map contains multiple agents).

The DMPC algorithm applied in this domain can be summarized as: Agents communicate with other agents and solve a finite horizon optimization problem in their local MPC controller, using the solution for action control. The optimization criteria are typically specified based on the agent's task.

In [26], the optimization problem is represented as 0–1 integer linear programming, and then a method based on the alternating direction method of multipliers (ADMM) is developed to coordinate AGVs and alleviate computational burden. [27] parameterises the trajectory of vehicles using polynomial splines, reducing the number of optimisation variables and achieving path tracking for vehicle platooning. [28] utilises a hierarchical DMPC (HDMPC) path prediction method with a trigger mechanism to control the behaviour of drones post-obstacle avoidance, achieving a more efficient multi-agent multi-different-target search in unknown areas compared to conventional methods. [29] addresses the issues of vehicle platooning control and obstacle avoidance by modelling the motion of an agent swarm based on animal behaviours. It then transforms the local MPC problem of the agent into a closed-form convex optimization. [30] utilises the grey wolf optimizer (GWO) to enhance the solution process of the DMPC controller, improving convergence speed and achieving 3D spatial path planning for multiple drones. [31] introduces a drone path planning algorithm based on predicting the motion of surrounding drones without the need for communication. However, this comes at the cost of increased computational load.

Overall, algorithm **research in this field focuses on three aspects:**

- Modelling and mathematical representation of the control task and the controlled subject.
- The communication topology of agents and their collaboration methods.
- Approaches to solving optimization problems, and the computational capabilities of agents is a significant limitation.

Furthermore, although this project utilizes the concept of DMPC to control and coordinate agent actions, **there are distinctions compared to relevant research in this domain:**

1. **Inter-agent Communication:** The algorithm in this project is based on a mature and reliable decentralized communication protocol (STDMA). Its implementation within the algorithm is essentially a simulation of this protocol. In contrast, most DMPC research typically omits the actual implementation of inter-agent communication, merely making assumptions about the communication capabilities between agents. Common assumptions include: Serial[26], agents communicating with others freely within a certain range[28]–[30], [32], directed graphs[33], [34]. On top of this, bandwidth limitations are occasionally overlooked[32].

2. **Target Scenario:** This paper investigates agent movements within a grid world[2] and multi-target path generation. However, the aforementioned DMPC studies predominantly focus on agent formation control or path-following within continuous space.

For the target scenario described in this project, there exists a category of algorithms specifically dedicated to addressing such issues: *Multi-Agent Path Finding* (MAPF).

## 2.3 Multi Agent Path Finding

The classical definition of the *Multi Agent Path Finding* (MAPF) problem is: **Multiple agents moving step by step in an undirected graph in discrete time**[35], which is precisely the target scenario of this project.

The MAPF algorithm can be divided into **several categories: classical, heuristic, rule-based, and machine learning combined**. Among these methods, those that are rule-based are the closest to the approach of this project.

- **Classical:** The most popular classic MAPF algorithm is the *Artificial Potential Field* (APF) algorithm, which put force fields around obstacles and goals to generate a force to guide the agents. APF methods does not guarantee collision-free and is prone to fall into local minima. There are still some research today dedicated to improving the performance of the APF algorithm, with a primary focus on optimizing the potential field function[36]–[38].
- **Heuristic algorithms** mainly include A\* and its variants (like D\* [39]). Heuristic algorithms mainly operate on the principle of searching for the optimal solution. Many researchers combine A\* with other algorithms to achieve better performance and goes beyond the original A\* [40], [41].
- **ML Combined:** The machine learning algorithm mainly used in this field is reinforced learning, and usually combined with other non-RL techniques [42]–[45].
- **Rule-based:** The rule-based methods are based on the idea that each agent follows a set of identical local decision-making principles (which means it is decentralized) and usually improve algorithm performance by modifying the rules. Most of these algorithms are

bio-inspired, including *Particle Swarm Optimisation* (PSO)[46], [47], *Genetic Algorithm* (GA)[48], [49], *Ant Colony Optimisation* (ACO)[50], [51], *Pegion Inspired Optimisation* (PIO)[52], [53] and *Grey Wolf Optimisation* (GWO)[54]–[56]. Apart from these bio-inspired algorithms, there is also a category of algorithms called push-and-swap[57], [58]. They address problems through two kinds of actions: push (move towards the goal) and swap (exchanging positions between agents).

Generally speaking, researches in this area are trade-offs between completeness, computational complexity, and optimality. There is currently no perfect algorithm for this question. Besides, direct communication between agents isn't always a key component in these methods (e.g. [39], [44]).

## 3 Algorithm

This section provides detailed information on algorithm and its implementation.

### Contribution Statement

The implementation of the STDMA protocol is provided by the supervisor<sup>1</sup>. Apart from this, all other components were independently completed by the author of this paper<sup>2</sup>.

### Environment

- **Hardware:** ROG Zephyrus M16 Laptop
  - CPU: 11th Gen Intel Core 17-11800H @ 2.30GHz
  - GPU: NVIDIA GeForce RTX 3060 Laptop GPU (unrelated to the experiment, information provided just for content completeness)
- **Software:**
  - OS: WSL2 (Ubuntu 22.04 LTS) in Windows 11 23H2
  - Implementation Platform: ROS2 Humble, all codes written in python

### 3.1 Communication with STDMA

This is the **first part of the algorithm: self-organised communication between agents**.

In STDMA, agents share a single channel by autonomously determining the serial speaking order, and the channel is represented with repeating frame with a certain number of discrete time

---

<sup>1</sup>[https://github.com/arthurrichards77/stdma\\_ros](https://github.com/arthurrichards77/stdma_ros)

<sup>2</sup><https://github.com/Vehshanaan/Dissertation2022>

slots. The approach to determining the speaking order involves agents independently assigning the right to use available time slots within the channel.

### 3.1.1 Synchronized Clock

STDMA requires agents to have synchronized clock.

**Assumption 1:** Agents have synchronized clock.

In practice, the synchronized clock is typically implemented with GPS. In the implemented simulation of this paper, it's **achieved using a ROS2 publisher and a topic**. A dedicated ROS2 node periodically toggles its member boolean value and publishes this boolean value to the clock topic each time it's toggled. This **creates a square wave clock signal with a 50% duty cycle** in the clock topic. Agents obtain the synchronized clock signal by subscribing to the clock topic.

### 3.1.2 Discretization of Channel Time

Agents consider a complete clock signal period (a high and a low) as one slot and consider a specific number of slots as a frame. Time frames continuously cycle, providing continuous and reusable slot resource for agents to use.

**Assumption 2:** The number of slots in a frame is predefined within the agents, and this parameter value is the same for all agents.

Please note that it is not necessary for each agent to have the same starting point for their frame. In other words, agents are permitted to have different frame starting point offsets.

The exact middle of each slot is the timing for message transmission. This divides a slot into two parts: before sending the message and after sending the message.

Figure 3.1: Illustration of the clock signal, slot structure, and the timing for message broadcasting within a slot.

### 3.1.3 State Machine for Channel Allocation

Agents employing STDMA go through four phases[1], with each phase representing a stage in an agent's integration into the network. Consequently, a state machine can effectively manage the process of an agent joining the network. Through progressive state transitions, the agent incrementally integrates into the network and secures its slot.

The implementation of this state machine in this paper is as follows:

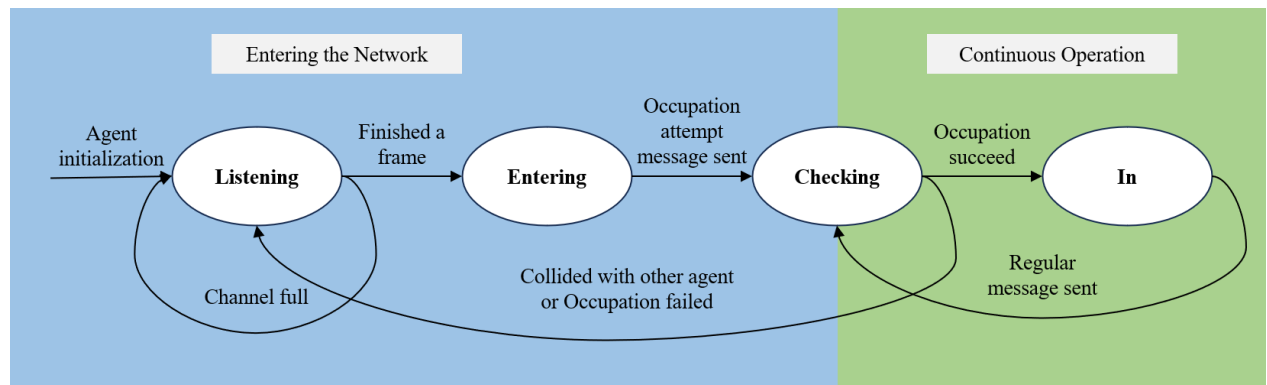

Figure 3.2: Schematic diagram illustrating the agent's state machine for managing STDMA.

#### 1. Listening

In this state, the agent's objective is to determine the current channel slot allocation by 'Listening' to the channel. Agents in this state have not yet joined the network.

**Slot allocation determination:**

In a slot:

- If only one message was sent: the slot is occupied by the sender.
- If multiple messages were sent or no message was sent: the slot is considered free.

The initial state of an agent is this state.

**Transition Condition:** After listening to a complete frame, the agent attempts to exit this state.

- → Entering: There are one or more unoccupied slots within the frame.
- ○ Listening: There are no free slots remaining in the frame. This suggests that the channel's capacity has been fully utilized, and the agent can only stay 'Listening' and remain idle.

## 2. Entering

In this state, the agent attempts to occupy a free slot in order to try 'Entering' the network.

**Transition Condition:** Agent randomly selects one from the free slots determined while in the 'Listening' state. Within this slot, the agent **transmits its unique ID** in an effort to occupy the slot.

- → Checking: The agent transitions to the 'Checking' state immediately after sending the occupation attempt message.

## 3. Checking

In this state, the agent has just broadcasted a message in a specific slot and must ascertain its ownership of that slot with the quantity and content of messages received within that slot. By 'Checking' its ownership of that slot, the agent transits its state.

Note that both agents that have not yet entered the network and those that have will transition to this state after sending a message.

**Transition Condition:** Transition the state based on the quantity and content of messages received in the slot where a message has been sent.

- → In: If only one message is received, and it's from itself (received ID = self ID), it indicates that the agent has ownership of that slot, meaning it is 'In' the network.
- → Listening: In *any other situation*: The agent does not have ownership of that slot and should try to secure a slot again.

**Explanation: All other situations include:**

- Didn't receive its own message: This suggests that either the broadcast was unsuccessful or the reception was unsuccessful (e.g., due to hardware damage or scheduled broadcasting being prevented, etc.). In both situations, we do not want the agent to enter the network, as its communication function may not be consistently reliable.
- Multiple agents sent messages within one slot (i.e. collision):

Collision Scenario 1: Multiple agents attempting to join the network coincidentally select the same slot. While such collisions are unavoidable within the context of this algorithm, they only occur among agents that have not yet entered the network and thus do not impact other normal communications.

Collision Scenario 2: A collision occurs between an agent that has already joined the network and one that has not. In theory, this type of collision should not occur, as agents not yet in the network should only attempt to occupy unoccupied slots. However, this situation may arise if an agent misses a clock pulse. Missing a clock pulse can cause an agent to fall out of synchronization with all other agents, potentially leading to conflicts and accidents. Efforts should be made to prevent this situation as much as possible.

#### 4. In

In this state, the agent is 'In' the network and should stay in the network until it releases its slot by stopping its regular message transmission.

Upon reaching their destinations, agents will shut down and release the slot they occupied in the channel.

**Shut Down and Release Slot:** An agent can release its allocated slot simply by ceasing to send messages within that slot.

#### **Transition Condition:**

- → Checking: After publishing a message, verify ownership of that slot.

## **3.2 Path Planning and Sharing**

This is the **second part of the algorithm: collision-free movement planning for multiple agents.**

### **3.2.1 Basic Framework and Definitions**

#### **Map**

The map is a grid world with obstacles, and the map information is pre-loaded into the agents:

**Assumption 3:** All obstacles in the map are stationary, and map information is pre-loaded into agents.

#### **Agent Capabilities and Constraints**

**Assumption 4:** Agents are identical.

#### **Capabilities:**

- Moving: Agents can choose to either remain stationary or move to an adjacent non-diagonal grid cell at each time step (corresponding to a time slot in the STDMA channel).
- Model Predicting: Agents can execute their own plans with complete accuracy.

**Assumption 5:** The agent's movement is not affected by external disturbances, and its prediction of its own motion is completely accurate.

Note: **Agents do not have perception of their surroundings**, and they achieve collision-free movement solely based on predictions of other agents' moves.

#### **Constraints**

- No Collision: Agents should not collide with each other.
- Obstacle Avoidance: Agents should not use positions on the map that are occupied by obstacles.

### Collision Definition

In this paper, the following two scenarios are considered as collisions:

- Two or more agents are located at the same 2D position on the map at the same time (Fig 3.3a).
- Two agents swapping their positions. That is, at time  $t$ , agent  $A$  is at position  $a$ , and agent  $B$  is at position  $b$ . At time  $t + 1$ , agent  $A$  is at position  $b$ , while  $B$  is at position  $a$  (Fig 3.3b).

(a) Collision Scenario 1: Two agents attempting to occupy the same position simultaneously.

(b) Collision Scenario 2: Two agents swap their positions.

Figure 3.3: Illustration of collision scenarios.

## Plan Definition and Constraints

### Definition

A plan is a sequence of 3D coordinate points  $(x, y, t)$ . Each coordinate point comprises a 2D location  $(x, y)$  and a specific time  $t$ , essentially indicating both the spatial and temporal aspects.

### Constraints

1. The points in the plan should align with the agents' capabilities and constraints (collision-free, move no more than one grid at a time).
2. The first point in the plan should be a non-diagonal adjacent point to the agent's initial position at the start of planning, and it must also satisfy the agent's other constraints.

## 3.2.2 Plan Broadcasting Method and Time Window for Planning

### Broadcasting

Through the channel facilitated by STDMA, agents broadcast their individual plans. This means **agents broadcasting their new plans and their IDs in the middle of each slot allocated to them** within the channel (see Fig 3.1 in Section 3.1.2).

Note that during plan formulation, only a sequence of 2D coordinates is generated, and time is implicit in the planning process. The time dimension of the plan is added by the recipient upon receiving the plan. As a result, only a set of 2D coordinate sequences needs to be transmitted each time broadcasting.

Additionally, there is a global parameter called "*plan length limit*", the length of the plan broadcasted each time window should not exceed this limit. The portion of the plan that exceeds this length will be truncated and abandoned.

**Assumption 6:** The plan length limit is predefined within the agents, and this parameter value is the same for all agents.

### Time Window for Planning

As previously mentioned in Section 3.1.2, each agent publishes their message in the middle of the slot allocated to it. Based on this rule, for every agent, **there exists a periodically repeating**

**time window where all variables (map, others' plans) related to planning are constant, and the agent's own plan can be immediately published as soon as it is formulated.**

This time window is the first half of the agent's own slot. Within this interval, no other agents would broadcast new plans, and as soon as this interval ends, the agent can immediately publish its own plan. This time window is **guaranteed to occur once in each frame** because it is a segment of a certain slot.

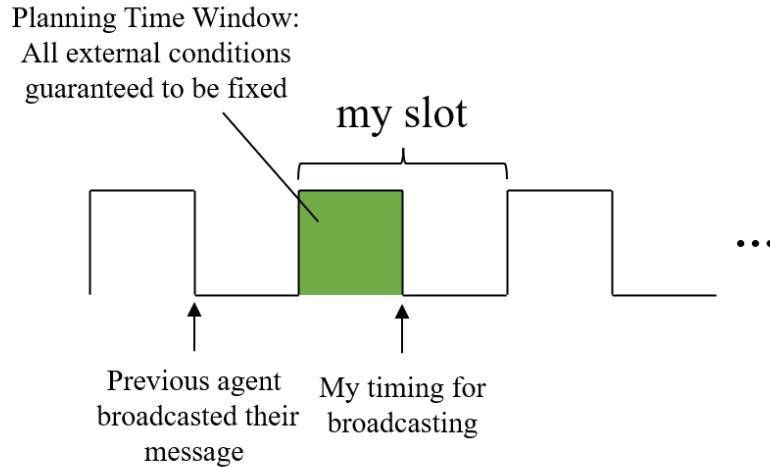

Figure 3.4: Illustration of planning time window.

### 3.2.3 Plan Generation

Each time planning, agent traverses all potential plans (i.e., paths) within the global parameter *planning horizon* that satisfy the constraints (moving capabilities and collision-free) and choose the plan that brings the agent closest (judged with Manhattan distance) to the goal.

**Assumption 7:** The planning horizon is predefined within the agents, and this parameter value is the same for all agents.

**Explanation on planning horizon:** Due to the computational limitations of the agent, it can only traverse a fixed distance into the future within each planning time window. This value is determined based on the agent's computational capacity.

**Method for traversing potential plans:** The agent employs the **A\* algorithm** to navigate the possibility space, adopting the Manhattan distance between the current position and the goal as the

heuristic function. Note that in this context, **the possibility space is a 3D space** composed of the 2D map and time.

### 3.2.4 Model Prediction

Agents generate plans that meet the constraints through model prediction.

#### Principles

Model Prediction is implemented based on two agreed-upon principles concerning agent behaviour:

- Principle 1: Agents would accurately execute all published plans.
- Principle 2: If a particular agent exhausts its own plan between two planning windows, it remains stationary **for the remainder of that frame**.

#### The Purpose of Principle 2 and the issues it generates:

**Purpose:** Decouple the frame length and the computational ability of agents.

Principle 2 ensures that agents always have an available default action and remain perceptible when their plans are exhausted (since agents percept each other solely through prediction). Without Principle 2, agents must generate a plan equal or longer than frame length, which imposes an unnecessary constraint on the frame length.

**Problem:** Given that remaining stationary is not a safety behaviour generated through planning, it can potentially result in collisions with the plans of other agents. **To prevent collisions, we must make sure no other agents have plans at in the time domain which one agent decides to remain stationary.** The global parameters *plan length limit* and *planning horizon* are in place to make sure of that. These two parameters guarantee that **all agents in the system broadcasts plans of the same length each time broadcasting.**

When an agent is planning, the leading edge of its planning horizon matches the leading edge of the entire system's predicting horizon (Fig 3.5). And no plan from any other agent could reach this far. Plans made by agents afterward will take into account the stationary position adopted by the earlier agents, ensuring no collisions

Figure 3.5: Illustration of 3 agents within a channel having a frame length of 3, where agents publish plans of equal length. This demonstrates why new plans are always on the frontier of the overall predicting horizon.

### Cold Start of Planning

'Cold Start of Planning' refers to the initiation of the planning process by an agent from its current position, **without inheriting any data from previous computations**. There are justifiable reasons for adopting this approach:

As previously mentioned, **agents are required to generate and publish plans of a fixed length each time they plan. This fixed length is constrained by worst-case scenarios**. In such scenarios, a newly published plan from a preceding agent may invalidate all unpublished plans of the current planning agent, leading to a cold start in the planning algorithm. **It is crucial to ensure that even in these worst-case scenarios, the agent can still generate a plan of fixed length**. Therefore, the bottleneck of plan length remains unchanged whether a cold start is implemented in the planning process or not.

Additionally, if the published plan spans more than a single frame, a portion of the plan would be in a state of having been published but not yet executed. **Even with a cold start, the newly generated plan will still include this unexecuted portion of previous plan**, as no new variables

could alter this solution (cannot have better solution: plan from other agents could only increase; cannot have worse solution: other agents avoid positions in published plans, and obstacles in the map are stationary).

### **The process of an agent entering and exiting the map**

#### **Entering the map:**

Since agents' awareness of each other relies solely on planning and consensus on default behaviour, **an agent is not known to others before it enters the network and successfully publishes a plan**, which can lead to potential collisions. Therefore, when an agent starts up, it does not occupy a position on the map; instead, it follows the following process to enter the map:

- The agent attempts to join the network.
- The agent tries to generate a plan with its starting point as the origin. If successful, it executes according to the plan (thus acquiring a place on the map). If unsuccessful, it repeatedly attempts to generate this plan.
- The agent operates continuously on the map.

Due to the subsequent experiments setting the starting points at the edge of the map, this process can be regarded as the agent's attempt to enter a specific area's network and subsequently its entry into that area.

#### **Exiting the map:**

Once an agent detects its arrival at the goal, it exits the map: it no longer holds a position within the map and relinquishes its slot in the channel (by ceasing to transmit information to the STDMA channel).

Due to the subsequent experiments setting the goals at the edge of the map, this process can be regarded as the agent exiting a specific area's network and leaving that area.

### **3.2.5 Path Planning Function and Implementation**

At the start of each planning window, the path planning function is called to generate the upcoming movement plan for the agent.

## **Inputs of the function**

### **1. map, agent's current position, goal, plans of other agents**

Foundational information required for the planning process.

### **2. first ever plan**

This is a boolean value that indicates whether the current plan is the agent's first plan upon entering the map, with an initial value of False.

This parameter is prepared for the aforementioned (Section 3.2.4) process of an agent entering the map. When this value is true, the first point of the plan must be the agent's starting point. When this value is false, the first point of the plan is selected from points adjacent to the agent's current position. Once the agent successfully generates its first plan, this boolean value is set to True.

### **3. planning horizon**

Previously mentioned in Section 3.2.3.

The upper limit of the time range explored within a single plan session. If a possible plan reaches this length, it will no longer be extended, and other potential plans that have not reached this length will be extended instead. If all possibilities within the horizon have been explored or a plan that reaches the goal has been generated, planning is stopped, and the plan that allows the agent to approach the goal most closely among the generated potential plans is returned.

### **4. plan length limit**

Previously mentioned in Section 3.2.2

The purpose of this parameter is to limit the maximum length of the returned plan. Only the portions of the generated plan that do not exceed this length are returned (and then published).

---

**Algorithm 1:** Path Planning Function

---

**Function** path\_plan( *map, current position (2D coordinate), goal (2D coordinate), plans of other agents, first ever plan, planning horizon, plan length limit* ):

current position  $\leftarrow$  set (current position, time = 0, cost = time + Manhattan distance  
(heuristic cost) of current position and goal, path = empty list)

frontier  $\leftarrow$  [current position]

visited  $\leftarrow$  set()

path list  $\leftarrow$  []

**while** frontier **do**

    current point  $\leftarrow$  pop the point with the lowest cost in frontier

    current path  $\leftarrow$  the path corresponding to the current point

    current time  $\leftarrow$  the time corresponding to the current point

**if** current path length = planning horizon **then**

        path list append current path

**if** current path length > planning horizon **then**

**continue**

**if** current point = goal and current plan length  $\leq$  plan length limit **then**

**return** current path

**if** first plan **then**

        neighbour  $\leftarrow$  start of the agent

**else**

        neighbour  $\leftarrow$  non-diagonal neighbour points of current point

**foreach** neighbour **do**

**if** (neighbour, current time+1) is not in visited and neighbour is valid **then**

            frontier append set(neighbour, time = current time + 1, cost = time +

            Manhattan distance of neighbour and goal, path = current path +

            neighbour)

            add (neighbour, current time+1) to visited

**if** path list **then**

        path  $\leftarrow$  the plan with the last point having the smallest Manhattan distance to the  
        goal

**return** The portion of the plan that does not exceed the plan length limit

**else**

**return** None

---

**Output of the function:**

If the agent is currently inside the map, generate a plan of the specified length starting from a position adjacent to the current position.

If the agent is not inside the map, generate a plan of specified length starting from the specified starting point.

If there is no plan meets the requirements, return None.

### **3.3 Summary**

#### **3.3.1 Assumptions:**

1. Agents are identical.
2. Agents have synchronized clock.
3. All obstacles in the map are stationary, and map information is pre-loaded into agents.
4. The agent's movement is not affected by external disturbances, and its prediction of its own motion is completely accurate.
5. The number of slots in a frame is predefined within the agents, and this parameter value is the same for all agents.
6. The plan length limit is predefined within the agents, and this parameter value is the same for all agents.
7. The planning horizon is predefined within the agents, and this parameter value is the same for all agents.

#### **3.3.2 Implemented Functions:**

After the agent is activated, it autonomously attempts to join the current communication network. After joining the network, it tries to enter the map from the specified starting point. Once inside the map, based on the movement plans of others and map information, it continuously searches for a collision-free continuous 2D coordinate sequence that can bring it closer to its goal, and broadcasts its own movement plan. When it reaches the goal, it releases its position in the communication network, exits the map and ceases activity.

## 4 Results

### 4.1 Experiment Design

#### Map

All experiments in this paper were conducted on a map simulating a warehouse scenario. This map was selected from a widely-used benchmark set[59]<sup>1</sup> for testing, due to its appropriate size and obstacle distribution.

Figure 4.1: The map used in the experiments. The outer border is not included in the map.

The size of the map is  $161 \times 63$  (the outermost green frame is not part of the map), with green representing obstacles and white representing passable areas. All narrow corridors (channels at the border and between obstacles) are one grid / pixel wide.

---

<sup>1</sup><https://movingai.com/benchmarks/mapf.html>

## STDMA Channel Slot Duration

Due to the necessity for agents to solve a finite horizon optimization problem within their allocated time slots, the duration of a single slot is constrained by the computational capacity of the agent. In the environment of this project (see Section 3), the duration of each **STDMA slot is set to 1 second**, allowing agents to set their **planning horizon to a maximum of 60**.

## Agent Initialization and Behaviour

### Starts and Goals Initialization

The starting points and their corresponding goal points for agents are pre-generated and stored in a launch file. During each experiment, all agents are started simultaneously, and then sequentially read the start-goal point pairs from this file and assign them to the agents as they are launched.

For example, if 50 agents are launched in an experiment run, the first 50 start-goal pairs in the launch file are read and assigned to the agents in order. The same approach is applied for different numbers of agents. This process ensures that **the initial starts and goals for the agents are certain and fixed upon each initialization**.

The starting points are located in the outermost circle of the map (the outermost green obstacle border in Fig 4.1 is not part of the map). The sequence of starting points is stored in the launch file after randomly shuffled. The goal points are on the opposite side of the map, and the mapping relationship between the starting points  $(x_{start}, y_{start})$  and the goal points  $(x_{goal}, y_{goal})$  is as follows:

$$x_{goal} = width(map) - x_{start} \quad (4.1)$$

$$y_{goal} = height(map) - y_{start} \quad (4.2)$$

Where  $x$  refers to the horizontal coordinate, and  $y$  refers to the vertical coordinate.

### Agent Behaviour

As previously mentioned in Section 3.2.4, after successfully joining the network, the agent attempts to generate a plan starting from the given start. If no plan meeting this requirement is

available, the agent is not present on the map (since the start is on the map boundary, **it can be considered as waiting outside the map**). If the agent reaches the goal, it will shut down and disappear from the map (since the goal is also on the map boundary, **it can be considered as exiting the map**).

## Parameters and Metrics

There are four adjustable parameters in the algorithm:

1. **plan length limit:** The upper limit of the length of the plan broadcasted each time broadcasting. Plans that exceed this length will be truncated and abandoned..
2. **planning horizon:** The upper limit of the future horizon that can be predicted in a single planning window, which is also the maximum length of the plan that can be generated in a single planning window.
3. **frame length:** The length of the frame in the STDMA channel, i.e., number of slots in a frame.
4. **agent number:** The number of agents.

There are five performance metrics:

1. **total path efficiency ratio:** sum of actual path lengths / sum of optimal path lengths. The optimal path is determined using A\* algorithm under the assumption that there are no other agents present in the map.
2. **average path efficiency ratio:** average of individual agents' path efficiency ratio (agent's actual path length / optimal path length).
3. **final agent arrival time:** the time at which the last agent reached its goal.
4. **average agent arrival time:** the average arrival time for individual agents.
5. **average network join time:** the average time spent by agents to join the network.

## 4.2 Experiment Results

### 4.2.1 Quantitative Results

Analyse the impact of parameter changes on system performance using quantitative results.

#### **plan length limit and planning horizon**

**These two parameters mainly impact the length generated plans.** The plan length limit sets the global maximum length for the broadcasted and applied plans, while the planning horizon determines the upper length boundary for plans that can be generated.

**A longer planning horizon is always more favourable**, as it allows agents to make effective actions within this range. Once plan exhausted, agents can only remain stationary until next planning window arrive (see Section 3.2.4).

On the other hand, **the plan length limit might have diverse effects when set longer or shorter:**

- Longer plan length limit: Sharing longer plans among agents, might enhance collaboration efficiency and overall effectiveness by enabling agents to coordinate over extended horizon.
- Shorter plan length limit: Sharing shorter plans among agents, could lead to more agile agent movements, potentially increasing efficiency by allowing for greater flexibility.

Additionally, **the plan length limit should be at least equal to the frame length.** This is because when the plan length is shorter than one frame, the agent will remain stationary, significantly reducing efficiency.

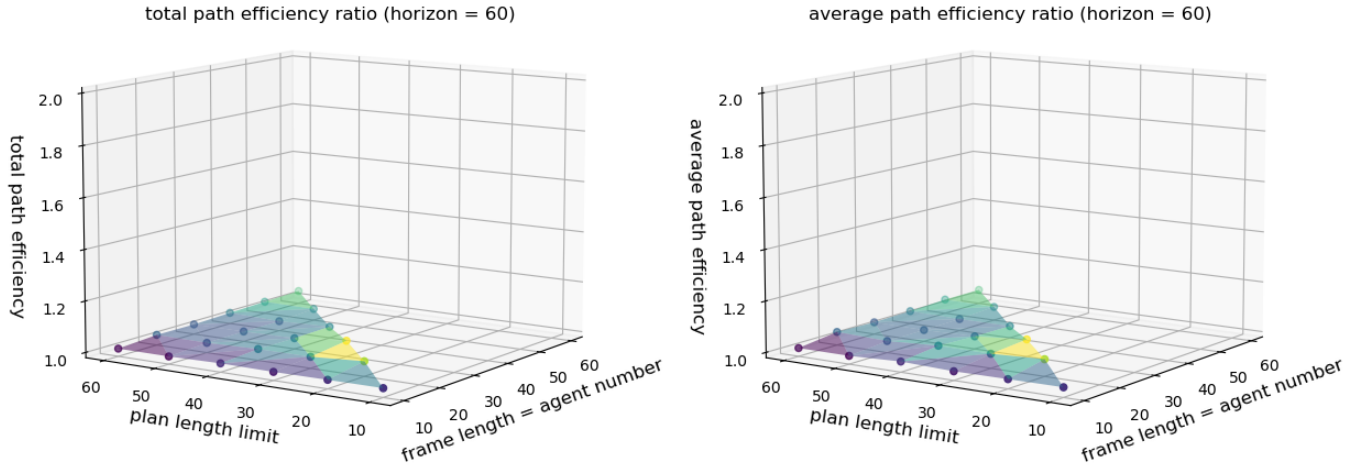

To validate these hypotheses, **two groups of experiments** are conducted as follows:

- **Group 1.1:** agent number = frame length, planning horizon = 30, plan length limit and frame length traverse a parameter space ranging from 10 to 60 in increments of 10. Notably, the plan length limit is always maintained to be greater than or equal to the frame length.
- **Group 1.2:** agent number = frame length, planning horizon = 60, plan length limit and frame length traverse a parameter space ranging from 10 to 60 in increments of 10. Notably, the plan length limit is always maintained to be greater than or equal to the frame length.

The random factor in the experiment is the time spent for agents to join the network, as agents randomly choose free slots in the channel when joining (see Section 3.1.3). Due to the considerable time required for the experiment (one slot takes 1 second), each point in the parameter space is tested only once. Although this approach doesn't eliminate all randomness, the trends indicated in the experimental results are still quite clear.

(a) Experiment Group 1.1: path efficiency versus plan length limit (planning horizon = 30)

(b) Experiment Group 1.2: path efficiency versus plan length limit (planning horizon = 60)

Figure 4.2: Performance versus Planning Horizon and Plan Length Limit. The vertical axis represents performance metrics, with lower values indicating better performance.

In Figure 4.2, the relationship between two metrics (total and average path efficiency) associated

with path quality and the planning horizon, as well as the plan length limit, is illustrated. The **results can be divided into two parts**: frame length > the planning horizon, and where the frame length < the planning horizon.

- Frame Length > Planning Horizon:

The slope in Figure 4.2a represents this part of results. Within this portion, the frame lengths are all greater than the planning horizon, indicating that agents remain stationary during the final part of each frame.

In this part, **the relationship between frame length and planning horizon predominantly influences path efficiency**. It's evident that both the total path efficiency and the average path efficiency nearly equal the ratio of frame length to planning horizon (as seen at frame length = 60, the ratio is near 2.0, for instance).

- Frame Length < Planning Horizon:

In Figure 4.2, all the flat parts represent the results of this part. From the graph, it's evident that when the frame length does not exceed the planning horizon, path efficiency remains almost unchanged regardless of variations in the plan length limit. The z-axis values in all these flat sections of the graph are below 1.05.

This indicates that **either the plan length limit has negligible impact on path efficiency, or the map is too open for the agents** involved in the experiment.

The explanation for the map being too open:

As mentioned in Section 4.1, although all the corridors have a width of only one agent's width (one grid / pixel), due to the specific distribution of obstacles, when a path is blocked, **an agent can simply choose to turn at different intersections to avoid collision**, this allows them to avoid the occupied corridors without sacrificing path efficiency. The setting of agent starting and ending points, as described in 4.1, might contribute to this situation. All agents need to cross the map, and **there are many optimal routes for crossing this map**, which could exacerbate the open nature of the map.

Overall, these experimental results suggest that, within the context of this test scenario, the plan length limit is not a critical factor. **Provided that the frame length does not surpass the planning**

**horizon, path efficiency may be sustained at a level closely approximating the optimum. If the frame length exceed the planning horizon, there would be a dramatic deterioration in path efficiency, and this is a situation that should be assiduously avoided.**

### **frame length and agent number**

**These two parameters are related to the system capacity.** Frame length refers to the quantity of slots within a frame, and agent number represents the number of agents initiated simultaneously at the beginning of simulation run.

**The advantages and disadvantages exist for both longer and shorter frame lengths:**

- Longer frame lengths: there is more channel space available for agents, allowing a larger number of agents to join the channel. However, if collisions occur during the joining process, according to the protocol (Section 3.1.3), agents need to re-listen to the entire frame to reconfirm the allocation and make another attempt to join. This time duration for re-listening increases with the longer frame length. Consequently, longer frame lengths do not necessarily lead to better outcomes.
- Shorter frame lengths: When the frame length is shorter, there is limited channel space, which can result in a significant number of agents lingering in the channel joining phase. This can lead to reduced efficiency. Although this scenario may not suffer from the prolonged re-listening disadvantage seen with longer frame lengths, the channel capacity is low due to the shorter frame length.

From this perspective, it is apparent that the magnitude of the frame length is relative to the agent number.

To investigate the impact of varying frame lengths on system performance, **the following experiments are conducted:**

- Group 2: The parameter space will be traversed twice with the following settings: planning horizon = 60, plan length limit = 60 (these two are independent parameters), agent number ranging from 10 to 60 with a step size of 10, and frame length ranging from 10 to 60 with a step size of 5. Certain points in the parameter space (specifically, those with agent numbers

significantly surpassing frame lengths) are omitted due to excessive time consumption and clearly inadequate performance.

Similar to the previous groups of experiments, the same random factor exists in this group as well: the randomness associated with agents randomly selecting free slots to attempt joining the channel upon entry. Due to the considerable time required for the experiment (with each slot taking 1 second), the parameter space is traversed only twice, and the average values of performance metrics are taken as results. Although this approach doesn't entirely eliminate randomness from the outcomes, the performance trends with parameter variations are still quite evident.

(a) Average agent arrival time results

(b) Final agent arrival time results

(c) Average network join time results

(d) Total path efficiency ratio result. It is evident from this graph that path efficiency is largely unaffected.

Figure 4.3: Experiment Group 2: Performance versus Agent number and Frame Length. The vertical axis represents performance metrics, with lower values indicating better performance.

There are only two factors that can influence the most important metric, which is the arrival time. These factors are: **(1)** the duration it takes for an agent to join the network, and **(2)** the efficiency of the agent's path.

In these two factors, the **path efficiency of the agent has almost no impact on the arrival time in this experimental scenario, as its variation across the entire parameter space is minimal.** As can be seen from Figure 4.3d, the efficiency of the agent's path is consistently high (all the points on the z-axis in the figure are below 1.05, which is in line with the results from the first group of experiments). The morphological similarity among Figure 4.3a, Figure 4.3b, and Figure 4.3c lends further credence to this observation, as the shape of the arrival time closely mirrors that of the time consumed by agents when joining the network. Although the final arrival time may deviate slightly due to higher randomness (as opposed to the average arrival time which is generated by averaging), the overall trend remains consistent.

**Consequently, the performance parameters in this scenario are primarily determined by the time it takes for an agent to join the network.** The variation in performance across the parameter space can be explained from this perspective.

As can be seen from Figure 4.3a, 4.3b, 4.3c, for each agent number, the points of **optimal performance tend to concentrate where the agent number and frame length values are close or equal.** Using the line where agent number = frame length as a reference, the results can be divided into two parts for discussion:

- Agent Number < Frame Length:

This part corresponds to the upper-right part of each figure in Fig 4.3. When the agent number increases relative to the frame length, there is a significant negative impact on performance.

This is because, in this part, the channel capacity is relatively limited, and a portion of agents must remain idle until available channel space emerges, allowing them to start their operations (entering the map).

- Agent Number > Frame Length

This part corresponds to the bottom-left part of each figure in Fig 4.3. As the frame length increases relative to the agent number, the performance gradually declines.

In this part, the channel has enough capacity for all the agents to operate in the network at same time. However, according to the protocol (Section 3.1.3), if multiple agents collides in the channel (accidentally trying to occupy the same free slot when entering), they must wait and listen through an entire frame before attempting again. This mechanism means that an excessively long frame length has a negative impact on the agent join time, as the extended frame length prolongs the time needed for each retry.

This explains why, for each agent number, **the points with the optimal performance are mostly when the frame length equals the agent number or slightly higher than the agent number**. In these cases, there is enough room in the channel to avoid having agents solely in idle mode, while the frame length is also not excessively long, preventing a prolonged process of retrying to join the network.

### **Channel Utilization**

For agents using STDMA to share channels, **the channels aren't always full**. In fact, **a portion of the channel is always contended for by numerous agents that haven't secured a slot**, leading to mutual collisions among them. This concern is investigated by examining the channel usage rate as a function of varying numbers of agents, while keeping the frame lengths constant.

One set of results from two repeated experiments in Group 2 is illustrated in Figure 4.4. While this method does not remove the element of randomness present in the experiment, the overall trend observed in the results remains unaffected by such randomness.

**From Figure 4.4, we can deduce the following points:**

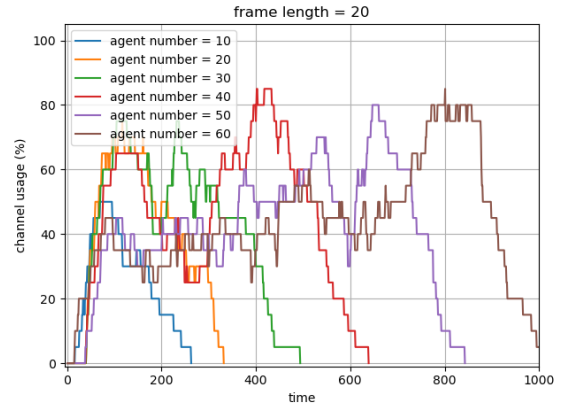

1. The highest channel usage rate is around 80%, excluding small-scale scenarios like 10 agents with a frame length of 10 as seen in Figure 4.4a.
2. The channel usage rate is higher when the number of agents is closer to the frame length.

This can be observed in two ways:

- The first curves in each figure to reach their peak are those where the number of agents is closer to the frame length.

(a) frame length = 10

(b) frame length = 20

(c) frame length = 30

(d) frame length = 40

(e) frame length = 50

(f) frame length = 60

Figure 4.4: Graph illustrating the relationship between the percentage of channel usage and time, for varying numbers of agents.

- If the number of agents far exceeds the frame length (e.g., Fig 4.4b, 4.4c), the channel usage rate for this group gradually increases. This is because the number of agents completed tasks rises, reducing the number of active agents in the system, making it gradually approach the scenario where the number of agents equals the frame length.

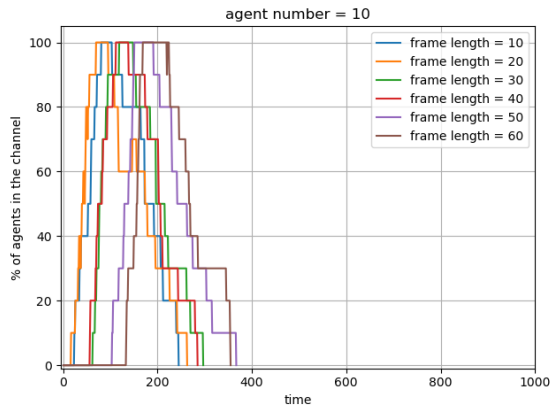

### Portion of Agents in Channel

In the implemented algorithm, **only agents present in the channel can publish plans and move within the map. Hence, the proportion of agents in the channel is worthwhile to take a look.** We delve into this matter by analysing the proportion of agents in the channel across different frame lengths.

The same dataset used for Channel Utilization observation is still employed here. In fact, the proportion of agents in the channel can be viewed as another perspective on Channel Utilization.

**From Figure 4.5, we can deduce the following points:**

1. Frame Length  $>$  Agent Number: More agents can enter the channel. However, **the longer the frame, the more time it takes** to reach the peak percentage, manifesting as a slower rise to peak values in the graph (e.g., Fig 4.5a).
2. Frame Length  $<$  Agent Number: The portion of agents in the channel drops notably. This decrease isn't solely due to the lack of enough space in the frame but also because **too many agents are contending for the available slots.** As agents progressively decrease (as they complete their tasks over time), the number of agents in the channel increases (e.g., the curve for frame length = 20 in Fig 4.5c, 4.5d, 4.5e, 4.5f).
3. Frame Length  $\approx$  Agent Number: The peak percentage of agents in the channel stabilizes at around 60%. This value increases with a rise in frame length and decreases as the frame length diminishes.

(a) 10 agents

(b) 20 agents

(c) 30 agents

(d) 40 agents

(e) 50 agents

(f) 60 agents

Figure 4.5: Graph depicting the correlation between the percentage of agents in the channel and time, across varying agent quantities and frame lengths.

### 4.2.2 Back-off Behaviours Arising from Optimal 3D Path Planning

Because agents are searching for optimal paths within a 3D space—consisting of 2D planar coordinates and time—it is observed that agents may take actions that appear as retreats when viewed from a 2D perspective. Some typical examples are illustrated in the figure below:

(a) Illustration of a narrow corridor with adjacent extra area. A utilizes the extra area to wait for B to pass.

(b) Illustration of an intersection meeting. A waits for B to cross before proceeding.

Figure 4.6: Illustration of typical back-off scenarios, wherein agent A formulates plans based on the plan received from agent B.

Such back-off behavior is unusual for algorithms that are solely focused on finding the agent's own optimal path within a two-dimensional space. **One reason for this is that the planning agent unconditionally avoids other agents** (as the generated plans must adhere to a collision-free constraint). Another reason is that in the implemented algorithm, **agents are conducting collision-free path planning within a 3D space composed of both 2D position and time. This expanded planning dimension grants agents a more nuanced and comprehensive decision-making perspective.**

### 4.2.3 Deadlock Situation

A deadlock situation arises only under exceptionally strict conditions.

## Condition

When the following conditions are simultaneously met, a deadlock between agents occurs:

1. Two agents are positioned within a sufficiently long corridor that's only one agent wide, each agent starts from different sides of the corridor and needs to reach the opposite end of this corridor.
2. The length of plans published by agents = frame length, i.e., planning horizon  $\geq$  frame length and plan length limit = frame length.
3. When one agent begins its planning, the other agent's plan should already be halfway executed, with only half a frame length remaining.
  - This yet-to-be-executed half of the plan should contain the current or adjacent position of the planning agent, which means this yet-to-be-executed part interferes the new plan of the planning agent.
  - The content of this half frame length plan should be solely directed towards its goal (advancing).

## Explanation

Because the characteristic of STDMA, the two agents make plan in turns, as their planning time window is their slot in the repeating frame. Additionally, agents publish plans of the same length throughout the entire system (see Section 3.2.4).

In this scenario, an agent's plan could be divided into two parts:

- Retreating: Due to collision-free constraints, when the other agent is moving forward in its plan, the agent must retreat to avoid collision.
- Advancing: When planning and in the later part of the planning horizon, the other agent's plan has exhausted (and at this point, the planning agent doesn't assume that another agent will idle after its plan ends, because a sufficient plan has already been published for it to use until its next planning window.). The planning agent could fill the rest part of its new plan with actions of proceeding toward its goal.

When the lengths of the advancing and retreating segments are equal, a dynamic deadlock scenario emerges: both agent spend half of their plans for advancing and the other half for retreating.

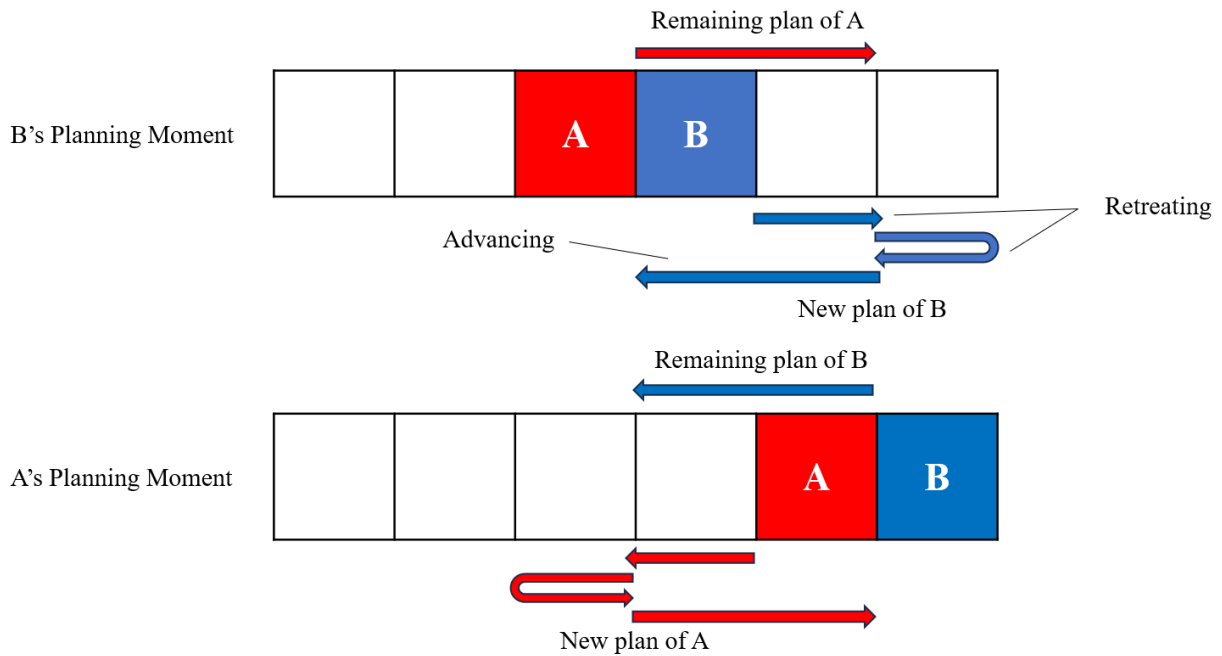

Figure 4.7: Example of a deadlock situation (frame length = 4, agent publishes plan with a length of 4).

## Solution

Due to the stringent requirements of this deadlock scenario, breaking any one of the three conditions will suffice.

For example:

- Use odd-numbered frame length: This breaks the tie between advancing and retreating, because these two parts cannot be of equal length.
- Avoid using long narrow corridors: Add additional area to the corridor, don't force agents to push each other.
- Allow agents to publish longer plans: If one agent requests an extensive span of space in their plan for advancing, the other agent will be compelled to retreat in the corresponding part of

its plan. This results in a highly imbalanced advance-retreat cycle, facilitating a swift exit from the corridor area.

This situation didn't show up in the quantitative result generating. This is mostly because the obstacles on our test map were relatively small compared to the planning horizon applied, so one agent could book all space in the corridor for advancing in one plan. Also, the conditions for this situation is quite strict.

#### **4.2.4 Failure Situation**

In the deadlock scenario, if there is a third agent, it could result in a failure: agent in the middle cannot find any possible plan.

##### **Condition**

1. Three agents are positioned within a sufficiently long corridor that's only one agent wide.
2. All agents are trying to get from one side of the corridor to the other, and one agent's starting and ending points are the complete opposite of the other two agents' starting and ending points.

##### **Explanation**

The primary reason this situation arises is due to the conflict between the two agents on the same side of the corridor. Since agents plan sequentially, the following scenario will always occur among the two agents on the same side:

- When the outermost agent (C in Fig 4.7) is planning, the inner agent's plan exhaust within the planning horizon, leading the outermost agent to believe it can keep moving forward, subsequently advancing to a position adjacent to the agent on the opposite side.
- When the inner agent (A in Fig 4.7, the one in the middle of the three agents) plans next, there isn't enough space for it due to the squeeze from the outer agent.

Figure 4.8: Example of failure. Due to the squeeze of agent C, agent A cannot find any possible plan (frame length = 4, agent publishes plan with a length of 4).

## **Solution**

- When the plan length that an agent can publish is sufficiently long relative to the length of the corridor, allowing an agent to reserve most of the space in the corridor in advance for its progression can prevent this situation (as seen in previous experiments where this situation didn't arise).
- Modify the consensus among agents. Currently, an agent only assumes other agents will remain stationary after their plans run out if the published plan length of the other agents is less than one frame (see Section 3.2.4). If, during planning, agents always assume that other agents will stay in place once their plans are exhausted, this situation can be avoided. However, it might lead to potential decreases in path efficiency.
- Avoid using overly long narrow corridors.

### **4.2.5 Local Optimal Trap**

When an obstacle is sufficiently large such that an agent cannot surpass it within the planning horizon, the agent can become ensnared in a local optimal trap. The agent will remain stationary at the position inside the obstacle that is closest to the goal, as it cannot reach a position closer to the goal within a single planning horizon.

This occurs because each time the agent plans, it only explores potential plans within a certain horizon and then selects the one where the final position is closest to the goal. If the planning horizon is long enough, this problem could be overcome.

Figure 4.9: An agent trapped in a local optimum due to a short planning horizon, preventing its arrival.

This situation didn't show up in the quantitative result generating. This is mostly because the obstacles on our test map were relatively small compared to the planning horizon applied.

# 5 Discussion and Conclusion

The conclusion needs to provide

- A short summary (What has been done and what are the main results)
- Limitations of your work, where applicable.
- Discussion of your work in the bigger picture (How does this contribute to the research field?)
- Future work (What could be next steps in this work?). Remember to keep future work realistic. A good approach is to discuss what the next progression of this project would be, and to justify why this would be interesting.

You will find it easier to write your conclusion if you copy-and-paste your *Aims*, *Objectives*, and any research questions or hypotheses you stated. You can then discuss each of these explicitly in turn, and how you were able to answer them or complete them successfully. When things have not gone as well as you would have hoped, demonstrate your critical thinking and reasoning to analyse the short-comings of your project - to demonstrate that you understand the underlying causes and that you could conduct good futurework from this learning experience.

# A Appendix

**This is optional.** Not every report needs an appendix. If you have additional information like code pieces, long tables, etc. that would break the flow of the text in the report, you can put it here.
